## 1 Introduction

In this work a summative and exploratory analysis of a patient-episode dataset will be conducted. This dataset has been provided by the Cwm Taf University Health Board and details the costs associated with treating patients during their time in hospital. The focus of this analysis is to better understand and observe variation in these costs; in particular, how a selection of cost-related attributes are distributed across the entire dataset and how they interact with one another. These attributes are comprised of non-trivial cost components and a set of clinical attributes typically associated with changes in costs. The ensuing analysis will show that while the bulk of the data corresponds to short-stay and relatively low-impact spells of treatment, there are long, heavy tails with high levels of variation in each of these variables.

Following this, a framework for the analysis of slices within the data is established, using the diabetic population as an example. This framework provides another dimension to the overall analysis through the use of comparison and contrast but the intended impact is ultimately lost due, again, to high levels of variation. Finally, the analysis looks toward other methods of extracting intrinsic structures built within the data. These methods are generally based in the clustering of patients and spells specifically, and so the framework is still applicable. There is also discussion of the clustering of patient pathways and how such analysis could highlight areas, procedures or departments that influence variation, and those that leave well enough alone.

#### 1.1 Data structure

Before any analysis can be conducted, it is best to learn how the data is structured and how it has been prepared. This dataset is comprised of approximately two and a half million episode records for patients from across Wales that were treated in the Prince Charles

and Royal Glamorgan hospitals (South Wales) from April 2012 through April 2017. An approximation for the geographic distribution of patients is given in Figure 1.

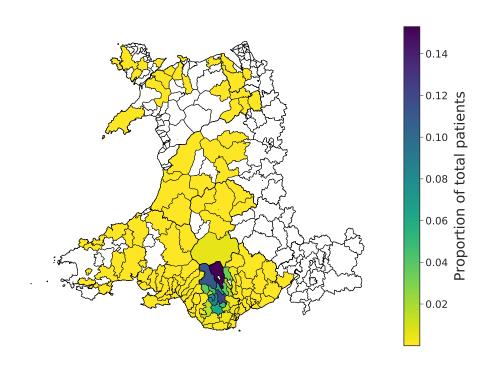

Figure 1: The proportion of total patients observed in the dataset by postcode district (e.g. CF24).

An episode is defined to be any continuous period of care provided by the same consultant in the same place. For instance, if a patient is admitted to a general medical ward for diagnosis and testing, and then is referred to a specialist consultant in oncology, then their first episode would end with their testing, and a second episode of care would begin on the oncology ward. Each of these episodes would correspond to a row in the dataset. If the patient was then discharged, they would have completed a spell with two episodes.

In this analysis, looking at episode-level statistics will be avoided in favour of a patient's spell-level statistics. Since the introduction of the 'payment by results' system for financial

flows, it has been seen that focusing on the more granular episode statistics can lead to the amount of resource or 'activity' consumed by a hospital to treat that patient being overestimated [1].

Each episode is recorded as a row of roughly 260 attributes or columns, including:

- Personal information such as identification numbers, age, registered GP practice;
- Clinical quantities such as the number of diagnoses made and procedures conducted in that episode, admission and discharge dates and methods, and length of stay;
- A number of cost components which include the costs coming from various departments within the hospital, overall medical and ward costs, as well as overhead costs;
- Diagnosis (HRG, ICD-10) and procedure (OPCS-4) codes, as well as Charlson index scores for the appropriate chronic diseases.

Of the attributes listed here, the focus is on the total, net and summed component costs, and a selection of other clinical variables - paying particular attention to those attributes which are considered to be linked to an overall contribution to the cost of care. Those attributes are: length of stay, the maximum number of diagnoses during a spell, the total number of procedures during a spell, and (separately) the number of spells associated with any given patient.

## 1.2 Cleaning the data

As with any real-world data analysis, a substantial amount of preprocessing and formatting was required to make the data sufficiently consistent and suitable for the intended purposes. This process included the removal of some superfluous columns which added unwanted redundancy to the dataset, and a number of rows that had been corrupted by some external storage software prior to this work's beginning. In addition to this, some columns have been reformatted; namely those whose entries were intended to be used as date-time objects later on. These include admission and discharge dates, and financial bench periods.

#### 2 An overview of the data

As was discussed at the end of Section 1.1, the majority of the attributes in the dataset will not be considered at this stage of the analysis. This allows the focus to be on how the costs of care are distributed and seen in the data. The subset of chosen attributes will frequently be referred to as the set of 'key attributes' but this choice of name does not imply that the remaining attributes are not of interest or that they are in any way unimportant.

The chosen, 'key' attributes provide a base for understanding how the costs and resources consumed by a patient in a spell are built up: cost components give direct information on which departments and types of procedures are being utilised; the length of stay can give an indication of the nature of the spell and any default costs that may be incurred by spending more time in hospital; and considering the maximum and total number of diagnoses and procedures (respectively) in a spell allow for some insight into the severity or complexity of a patient's spell in hospital.

#### 2.1 Distributions and summative statistics

When looking at the distributions of the key attributes on the whole dataset, displayed in Figures 2 - 6, it is clear that the data is weighted towards low-cost, short-stay, and

otherwise low-impact patients. This behaviour is well-projected through Figures 2 & 3. Here, it is clear that of all the spells provided under the care of the health board that the majority are day-cases, and that the patients being dealt with are one-time users of the hospital system.

In general, the distributions themselves have long, pronounced tails. This suggests that the effect of extreme cases, despite being a rarity, takes a toll on the hospital system with respect to the cost of providing care.

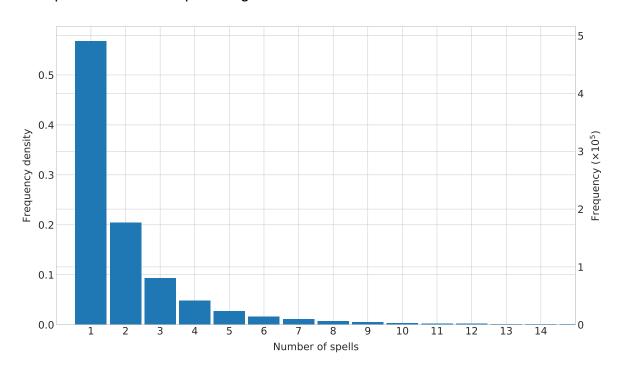

Figure 2: Bar chart for the number of spells associated with a patient.

Though the length and returning frequency of the spells are largely minimal and tightly packed, their associated net costs are wildly variant. This is seen immediately from inspecting Figure 6. It would appear that there is a distinct peak in the figure, but upon closer inspection of the scale it becomes clear that this peak is little more than a blip; the most probable net cost has a likelihood of less than one tenth of a percent. The remaining values are distributed in a way that, given the scale, is near uniform, spanning

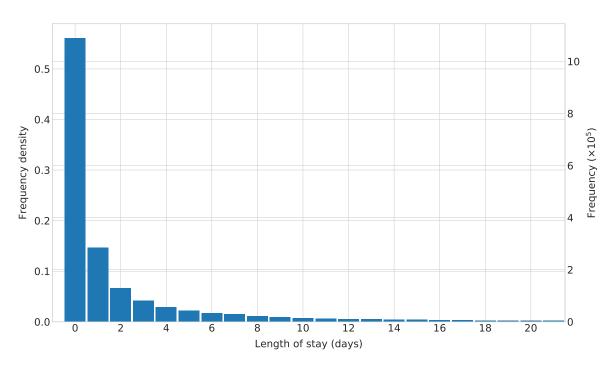

Figure 3: Bar chart for the total length of a spell, clipped at 21 days. Maximum 705 days.

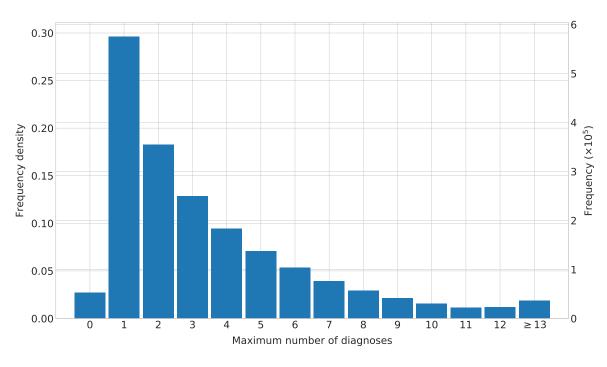

Figure 4: Bar chart for the maximum number of diagnoses in a spell.

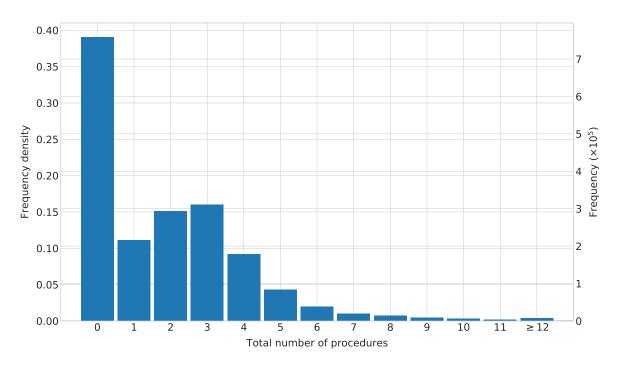

Figure 5: Bar chart for the total number of procedures in a spell.

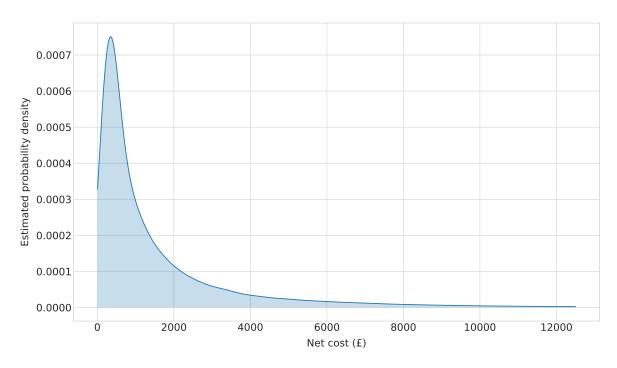

Figure 6: Estimated probability density for the net cost of a spell, clipped at £12,500. *Maximum approx. £369,000.* 

from approximately £6000 up to £369,000. A more detailed look at the skeleton of this distribution, and those of the remaining key attributes, is given in Table 1.

Table 1: Summative spell-level statistics for each of the key attributes.

Health-related analyses classically categorise patients by grouping ages together to aid the calculation of risk factors and projected costs. This has proven to be particularly helpful when looking at older patients [2]. Baring this in mind, looking at how age is distributed amongst the patients in the dataset can provide another valuable insight into how costs appear.

Figure 7 shows this distribution in contrast to a UK population estimate in 2016 from the ONS. Following the graph from left to right, the UK estimate is roughly uniform from birth up until the late 50s where a decline appears as older people become less prevalent. Looking instead at the patients in the data it is clear that there are several peaks and

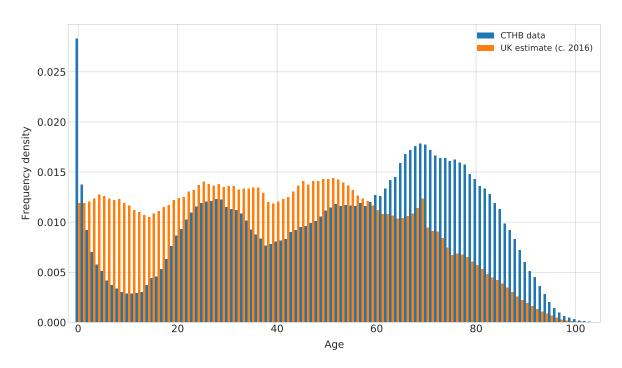

Figure 7: Bar chart for the age of patients in the dataset against the estimated UK population in 2016.

troughs. The largest trough corresponds to adolescents which makes sense since some of the least likely people to visit a hospital would be reaching their peak fitness biologically. Similarly, the clear peaks around infancy and in the older age range correspond to those people who are most vulnerable in terms of their health. Thus, a hospital should expect to see a disproportionate number of them.

#### 2.2 Pairwise correlation

By looking at the distributions of the key attributes in the previous section, a surface-level understanding of the data was established. The next logical step is to dive deeper into the data and investigate how these attributes interact with one another. In this analysis, correlation coefficients will be used to give a sense of this interaction.

Figure 8 shows the Pearson correlation coefficient of all pairs in the subset of selected

attributes. The data has been presented in the form of a heat map with a colour bar located to its right, indicating the scale of the correlation between any two variables. Using a visualisation such as this is more intuitive than reading directly from the corresponding array of numbers, and makes gaining insight from the relationships between variables much easier.

The attributes themselves have been arranged into descending order according to their summed absolute correlation coefficient. Doing this makes it easier to deduce which variables have the most prominent levels of interaction.

**Definition 1.** Consider a dataset with  $m \in \mathbb{N}$  attribute columns, denoted by  $A = \{A_1, \dots, A_m\}$ . Attribute  $A_i$  has associated with it a summed absolute correlation coefficient,  $c_i$ , given by:

$$c_j = \sum_{k=1}^m \left\| \rho_{A_j, A_k} \right\|$$

Here,  $\rho_{A_j,A_k}$  is the Pearson's correlation coefficient between attributes  $A_j$  and  $A_k$ .

Upon inspection of the heat map, there are many cost components that have no significant linear correlation with any of the other attributes. Despite this, however, there are clear correlations between many of the attributes; some of these are easier to realise than others.

For instance, ignoring the main diagonal, the largest value is that between total costs (COST) and net costs with a value of 0.94. This indicates almost total positive linear correlation between these two variables, and that makes sense given that the net cost of a spell is just the total cost corrected for a number of reimbursable costs like critical care (CRIT) and non-contracted income (NCI) which are entered as negative values in the dataset - hence their distinctly negative correlation coefficients with the other variables. Typically, these deductible costs are small (see Table 1) so a strong correlation between costs and net costs is to be expected.

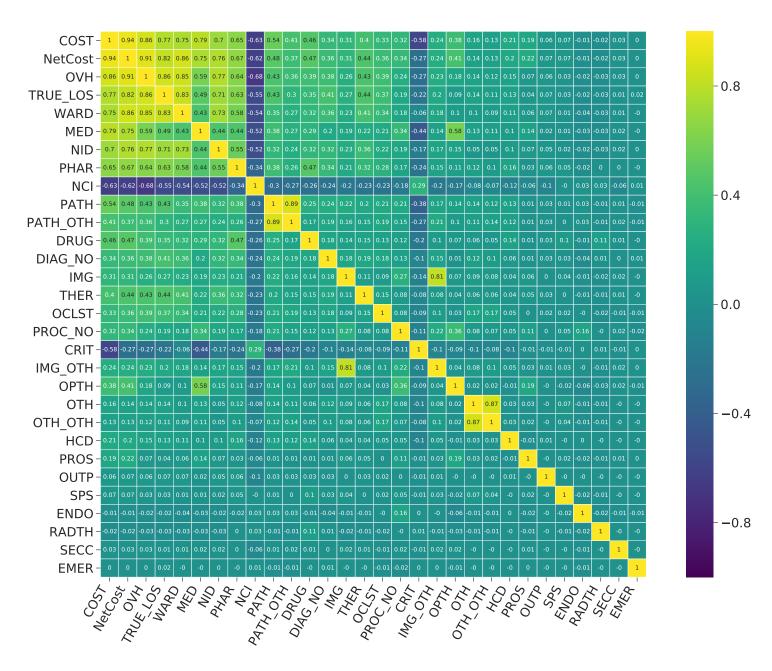

Figure 8: A heat map of the pairwise correlation coefficients for the key cost attributes. The attributes have been ordered according to their summed absolute correlation coefficient.

Another example is the strong correlation amongst the length of stay (TRUE\_LOS), and ward and overhead costs (WARD and OVH respectively). These are well-known relationships that can be justified anecdotally: the longer a patient spends in hospital, the more time they are likely to spend on a ward. Thus, incurring associated overheads like administrative work, cleaning costs and a larger proportion of rental costs. It should also be clear that these attributes all share a strong linear correlation with the net cost of a spell. This suggests that these costs and the length of stay are strong indicators of the net cost of treating someone, and may suggest that the remaining cost components make up a substantially smaller part of the net cost.

## 2.3 Measuring variation and importance in our cost components

The larger purpose of this work is to better understand the factors leading to some variation in the cost of treating patients so it would be fitting to investigate how this variation appears in each of the cost components. By doing so, a high-level indication of which departments and procedures that impose more (or less) variation can be established. Once a level of variation has been determined, the relative importance of that component and its variation can be assessed by considering the overall contribution that component makes to net costs.

In this section, and throughout this analysis, a dimensionless measure of variation will be used so that the components can be compared against one another in the same context. This measure is known as the coefficient of variation and is effectively a scaled standard deviation. During the early stages of this analysis it was found that the conclusions being made around the variation in each cost component were flawed since variation was measured using the classical unbiased sample variance. While this quantity is perfectly valid and an unbiased estimator for the population variance, it is dependent on the scale

of the data being considered. The effect of depending on this measure is still evident in Table 1.

**Definition 2.** Consider a population with mean  $\mu$  and standard deviation  $\sigma$ . Then the coefficient of variation, denoted by  $C_v$ , is defined to be:

$$C_v := \frac{\sigma}{\mu}$$

If only a sample of the data from a population is available then the coefficient of variation can be estimated using the sample standard deviation and the sample mean analogously.

In Figure 9, the coefficient of variation for each of the cost components is shown as a bar chart. The components have been ranked as in Figure 8 from the most to least correlated. It is immediately clear that there are a number of strongly variant cost components. Take outpatient costs (OUTP) as an example: its standard deviation is over thirty times the size of its mean. This could go some way in explaining why there seemed to be no linear correlation with the other variables in Figure 8 since these costs are so wildly varied.

At the other end of the chart, ward and overhead costs have some of the smallest variations. This would suggest that they are in some way consistent or predictable, as was commented on in Section 2.2. Despite this, the dominant conclusion is that all of the cost components are still quite highly varied when considering the entire dataset since the majority of coefficients of variation found have size far greater than one.

At this point, knowing which of the cost components are the most highly varied is not sufficient to decide whether they are worth pursuing further. In order to determine the relative importance of these findings, the contribution of each cost component to the net cost of a spell must be considered. Then, with a sense of the scale of the variation

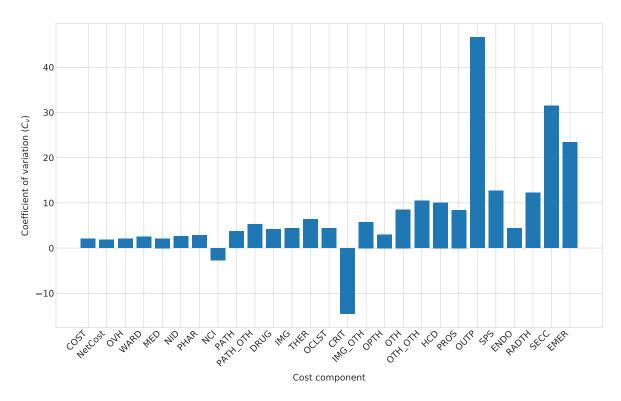

Figure 9: Bar chart showing the coefficient of variation  $C_v$  of each cost component, and the net and total costs.

acquired, the components that make the most significant impacts on net costs can be isolated. These quantities are calculated by taking each cost component in a spell, dividing it by its corresponding net cost and taking the mean over all of these values. This mean is referred to as the average contribution (or proportion) to the net cost, although it is more accurately an average of the spell-wise ratios between each cost component and the net cost.

By inspecting Figure 10, it is seen that ward, overhead and medical (MED) costs are the largest contributors to the net cost of a spell by a large margin. When looking across the remaining bars, the contribution is substantially smaller for the department-specific cost components. Not only that but it appears that the most varied components (from Figure 9) have near negligible average contributions to the net cost of a spell.

So the question left to be answered is: can these small but highly varied components

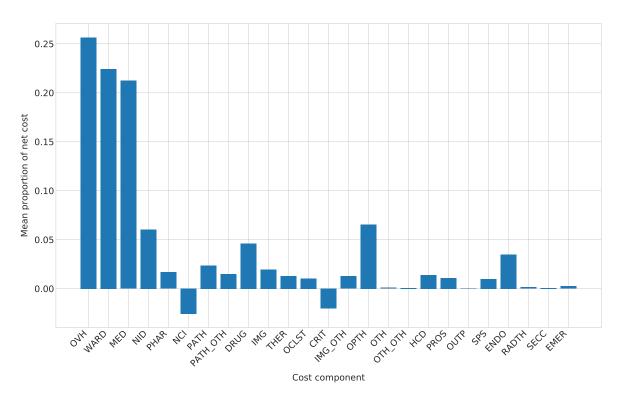

Figure 10: Bar chart showing the average contribution of each cost component to the net cost of a spell.

be considered especially important? And what about the other components? The midriffs of each of these figures contain many of the same components but the relationships are less clear. In order to attain some understanding of how these two quantities relate to one another, a bubble plot is used. Such a plot allows for three-dimensional data to be displayed in the two-dimensional plane; by running their common variable along the horizontal axis, both of the quantities can be visualised together by using the vertical axis and size as two separate dimensions, as illustrated in Figure 11.

This figure can be interpreted either by first reading along the vertical axis to find the components that make the most considerable contribution to treating a patient, and then investigating the variation that component holds by looking at the size of its outer marker. The reverse of this process is also perfectly logical since the objective is to determine where the variation exists, and then how much of an impact that has on the net cost, as

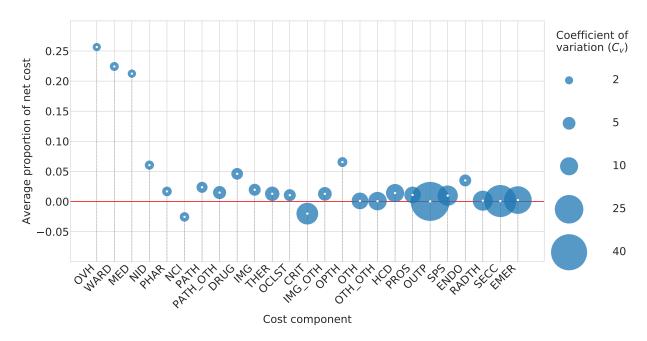

Figure 11: A bubble plot showing the average contribution to the net cost of a spell along the vertical, and the coefficient of variation for that component as the size of its marker.

has been done above. The crux of interpreting this plot is that the further away a large marker is from the zero line, the more important that component is to be considered. However, small markers are also of interest since these components indicate that the level of variation is relatively low - the reasons as to why are still unknown.

It is easily seen from this figure that the conclusions made previously still hold. That is, the largest contributors have some of the smallest measures of variation while the smallest average contributors are more strongly varied. What is of interest is the jump between these groups of cost components. There does not seem to be any particular component in the midriff of contributors that has large, or indeed small, variation. This suggests that a deeper investigation is required to properly analyse individual components and their relationships with specific types of patient.

## 3 Taking a slice: diabetic patient analysis

The main conclusion to be taken away from the previous summative analysis is that the dataset contains a huge amount of variation. Therefore, in order to conduct more meaningful analysis, more homogeneous subsets of the data must be considered.

Classically, patients are categorised by age or condition. However, it has been shown that doing so often gives an unrepresentative slice of patients [6]. In this section, the focus will be on the diabetic population within the dataset despite this potential danger as it provides a good example of condition-based slicing and is of interest to public health groups.

Since diabetes is recorded only as a primary or secondary condition in the dataset and is not distinguished by type, the diabetic population is considered to be any instance where diabetes is present.

The ensuing analysis will provide evidence that the diabetic population is increasing in the Cwm Taf area, and that, despite this, the relative resource consumption by diabetic patients has been stagnant over the data period. It will also be seen that this population holds too much variation to make meaningful conclusions about the population on the whole. However, by considering a subset based on a condition such as this, there is a natural opportunity to compare the subset with its complement; by considering the differences and similarities between these two datasets a new dimension is added to the analysis.

#### 3.1 Distributions and summative statistics

In much the same way as in Section 2.1, taking an overview of the key attributes provides some idea about how costs are represented in the data. Figures 12 - 16 show the same statistics as in the summative analysis though these figures have two additional compo-

nents: (a) in the case of bar charts, separate plots for overall frequency and frequency density, and (b) a comparison with the non-diabetic population on the same axes. The purpose of the separate bar charts is to show, firstly, the relative sizes between the groups and their bins, and then to be able to directly compare their distributions.

As before, the distributions of the diabetic population have long tails but they are often heavier than the general or non-diabetic populations which are arguably interchangeable given their sizes. This extra weight in the tails suggests that diabetic patients are more likely to experience severe periods of illness, and this is bolstered by the complete difference in the shape of the distribution of maximal diagnosis numbers pictured in Figure 14.

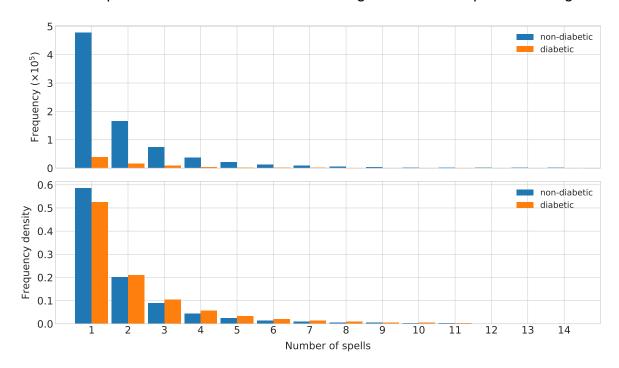

Figure 12: Bar chart for the number of spells associated with a patient in the presence of diabetes and not.

Other than diagnosis numbers, the shapes of the distributions here are comparable. As stated, the tails are heavier across the board for the diabetic population. With that being true, it follows that the noses are substantially lighter. This is evident most clearly in Figures 12, 13, 15 & 16 which imply that diabetic patients are more likely to return, have

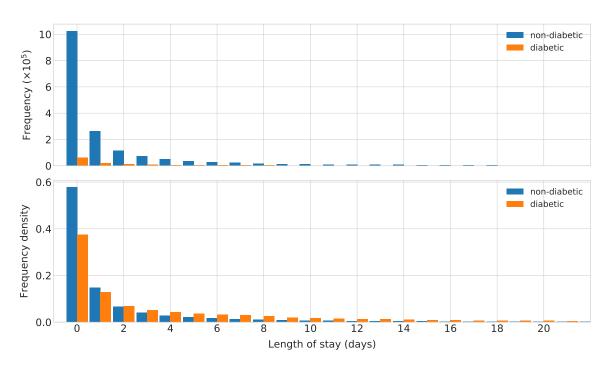

Figure 13: Bar chart for the total length of a spell in the presence of diabetes and not, clipped at 21 days. *Maximum 705 days*.

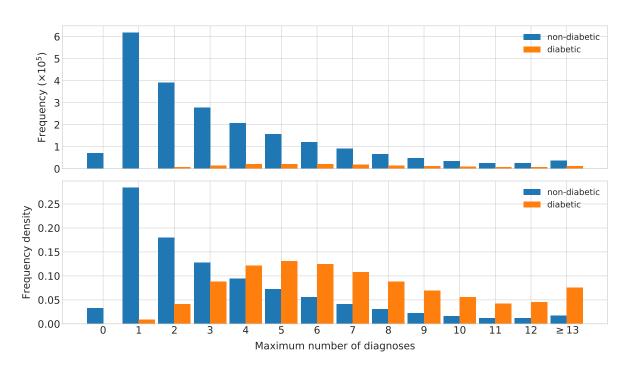

Figure 14: Bar chart for the maximum number of diagnoses in a spell in the presence of diabetes and not.

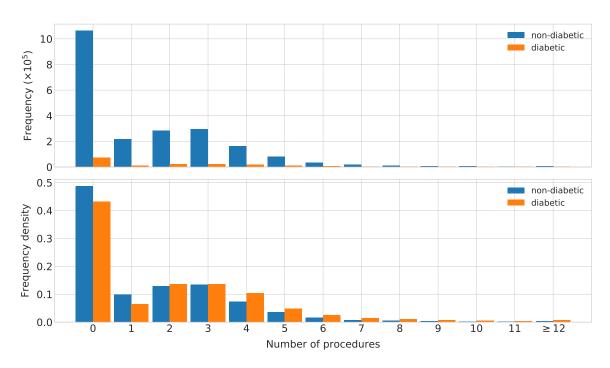

Figure 15: Bar chart for the total number of procedures in a spell in the presence of diabetes and not.

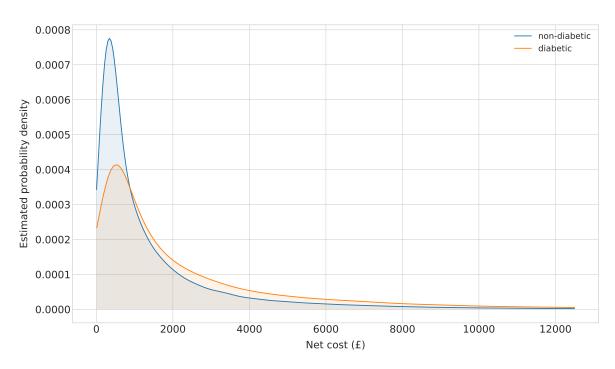

Figure 16: Estimated probability density for the net cost of a spell in the presence of diabetes and not, clipped at £12,500. *Maximum approx.* £369,000.

more procedures and stay longer in the hospital whilst typically incurring higher costs than non-diabetic patients. These all suggest that diabetic patients represent a population of patients and spells that are more severe on average than the typical patient, and thus will likely have a larger effect on the hospital system on the whole. Again, a more detailed breakdown of the skeleton for each of these attributes as well as the other key attributes is given in Table 2. This table also shows a comparison between both populations being considered in this section.

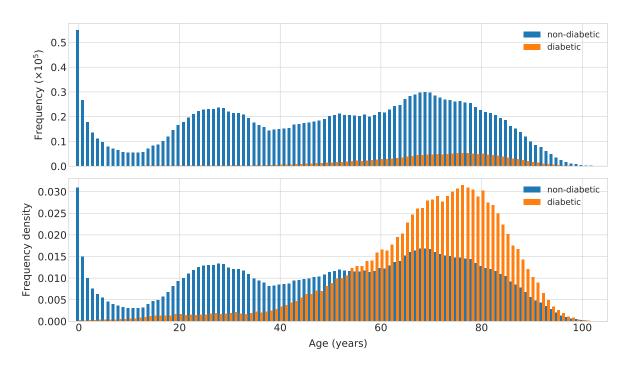

Figure 17: Bar chart for the age of patients in the presence of diabetes and not.

The distribution of patients' age is given in Figure 17 and quite clearly shows how unrepresentative a slice the diabetic population can be - as was discussed above. Here, when looking at the frequency density plot, all the intricacies in the shape of the age distribution for the entire dataset and the non-diabetic population are dropped. Instead, the distribution indicates negative skew and disproportionate amount of older patients. Thus, considering the diabetic population is similar to just considering older patients since

they dominate the population.

However, the small number of younger diabetic patients that remain could be polluting the population and this analysis. A remedy for this would be to consider two or more diabetic populations based on their age and perhaps a combination of other attributes including severity or total cost. Deciding meaningful populations like these would require a large amount of potentially arbitrary splitting on, or estimation of, such attributes. As such, these methods will be avoided since they are not guaranteed to be appropriate or robust.

#### 3.2 Pairwise correlation

With an overview of how the key attributes are distributed in mind, as before, it is a good idea to see how these attributes interact with one another. In Figure 18, the Pearson correlation coefficients are shown between each of the pairs of the key attributes in the diabetic population. Again, the attributes have been ranked in descending order according to their summed absolute correlation coefficient (see Definition 2.2) to determine those with the highest levels of interaction.

To more clearly see the subtleties between these correlation coefficients and those in Figure 8, another heat map has been included to show their differences in Figure 19. This heat map utilises a different colour map to reflect this, and the attributes have been ranked in descending order of their summed absolute differences. From this figure it is seen that drug and therapy costs (DRUG and THER respectively) have the largest total difference in correlation coefficients. In fact, the sign of these differences are in line with those coefficients in both of the previous heat maps meaning that these attributes are more strongly correlated amongst diabetic patients than for the general population.

However, other than a small number of attributes at the top, this difference heat map

	COST	NetCost	CRIT	DRUG	EMER

Table 2: Summative spell-level statistics for each of the key attributes. In each column the diabetic population's statistic in followed by the corresponding non-diabetic statistic in brackets.

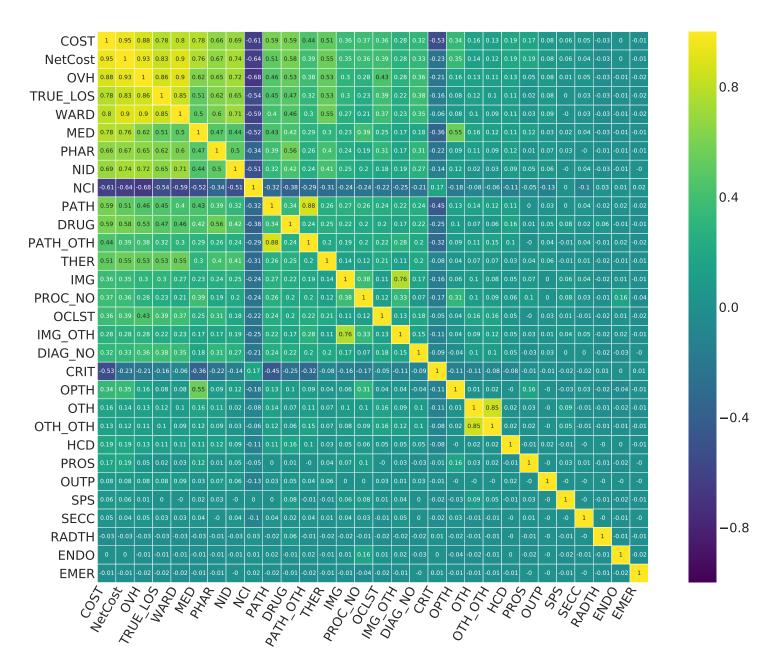

Figure 18: A heat map of the pairwise correlation coefficients for the key cost attributes in diabetic patients. The attributes have been ordered according to their summed absolute correlation coefficient.

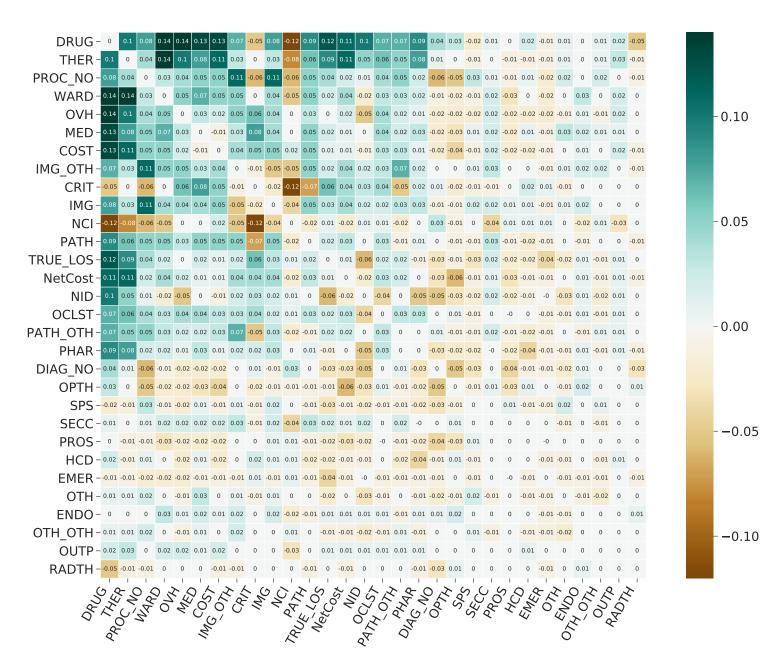

Figure 19: A heat map of the difference in pairwise correlation coefficients between the diabetic and general populations. These attributes have been ordered according to the sum of their absolute values.

shows that the vast majority of correlation coefficients are unaffected by considering the diabetic population alone. Given the large amounts of variation and low levels of correlation seen in Section 2.2, this is unsurprising but where there are differences suggests potential areas of interest when comparing the corresponding diabetic variation with the non-diabetic and general populations.

#### 3.3 Variation and relative importance

Again, it has been established how the key attributes are distributed and interact in both the diabetic and non-diabetic populations. From here, the remaining component of the methodology established in Section 2 is to investigate variation and importance. Figures 20 & 21 show these quantities, and are ranked as in Figure 18.

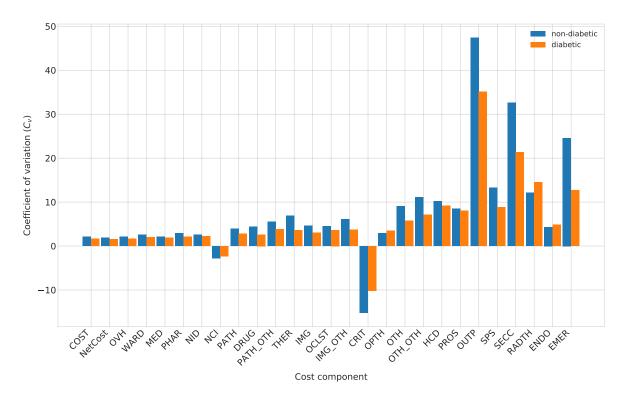

Figure 20: Bar chart showing the coefficient of variation  $C_v$  of each cost component, and the net and total costs, in the presence of diabetes and not.

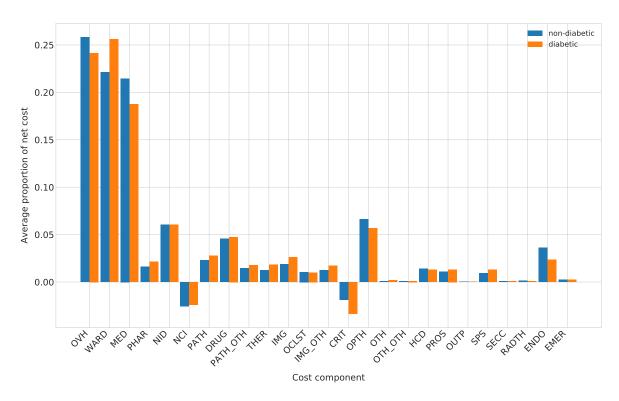

Figure 21: Bar chart showing the average contribution of each cost component to the net cost of a spell in the presence of diabetes and not.

Aside from the change in the order of the attributes compared with Figure 9, this plot is largely similar: more weakly correlated attributes tend to be more highly varied and the overall level of relative variation is high. Having said that, the diabetic population is consistently less than, or similarly, varied in each instance except operating theatre (OPTH), radiotherapy (RADTH) and endoscopy (ENDO) costs which implies that this subset of the dataset is in fact somewhat more homogeneous, as desired.

Inspecting Figure 21 tells a similar story as with the general population. That is, the dominant cost components are still overheads, medical and ward costs, and the least correlated (and often most varied) components are insignificant in their contribution to net costs. However, there is a certain interest in the increased contribution from ward costs and those from specific departments such as pharmacy (PHAR), pathology (PATH), and imaging (IMG). The apparent increase in the likelihood, severity and length of diabetic pa-

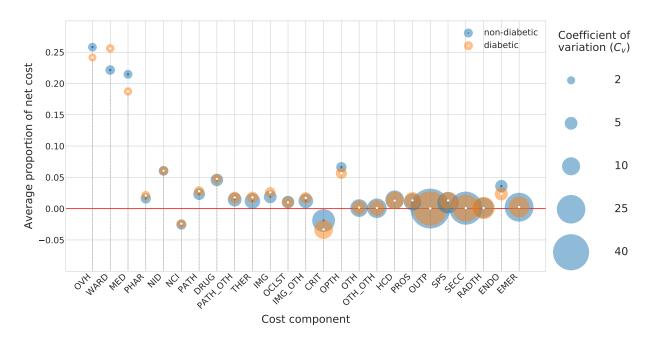

Figure 22: A bubble plot showing a comparison between the diabetic and non-diabetic populations' average contribution to the net cost of a spell along the vertical, and the coefficient of variation for that component as the size of its marker.

tient spells seen in Table 2 - and alluded to by the heavier tails in Figures 12 - 15 - seems to be linked to a rise in costs more generally which can be rationalised given that this population all exhibit at least one chronic disease that is known to have several comorbidities and knock-on effects more widely associated with a patient's well-being [3] [5] [7].

In much the same way as in the previous section, the bubble plot shown in Figure 22 allows these quantities to be considered simultaneously, and again, there is little to gain from its information. There are no distinctly important components here and the system seems to be optimised for both the diabetic and non-diabetic populations. That is, to the point where the smallest relative variation of a component is still twice its mean.

So what was there to gain by looking at the diabetic population? From this surface-level analysis, it was found that the diabetic population is marginally more homogeneous than the general or non-diabetic population but that it still exhibits a large amount of variation. This was to be expected since the decision to look at diabetic patients was effectively

arbitrary, and was not descriptive enough to indicate that any particular kind of patient was being investigated other than that they must exhibit this one condition. So, in that way, there was little to gain. However, as has been noted throughout this analysis, taking a subset of the population allows for some comparison with its complement (depicted in most Figures 12 through 22) as well as the entire dataset. Comparisons of the latter form will be discussed further in the remainder of this analysis.

## 3.4 Resource consumption

The types of comparisons made between the non-diabetic and diabetic populations throughout this analysis are useful for observing their similarities in a direct way, and in understanding how the groups may relate to one another.

However, these are not the only devices available for examining such a subset of the data. Particularly when looking at costing data such as this, another useful way of evaluating a subset is to quantify its size and representation in the data with respect to various cost-indicative attributes. These attributes can give a sense of the level and nature of the resources that are consumed by the population in question. Namely, these attributes are: the proportion of total net costs and admissions, and length of stay. During this part of the analysis, these attributes will be referred to as the "chosen" attributes.

In addition, whilst considering that costs are the focus of this body of work, it can be useful to investigate how certain cost-related quantities evolve for a subset of the population. In this section of the analysis, the evolution of the aforementioned attributes will be discussed within the diabetic population as a part of the general data population. For these purposes, the data must be manipulated into a chronological form and so some approximations have to be made. Here, each of the chosen attributes is given with respect to a particular admission date, and has been calculated in the following way for each

#### admission date:

- **Proportion of total admissions:** Take the number of unique spells for diabetic patients admitted on that day,  $n_d$ , and the total number of unique spells with that admission date, N. The proportion of total admissions on that day from diabetic patients is given by  $\frac{n_d}{N}$ .
- Average length of stay: Take the mean over all lengths of stay from the diabetic spells with that admission date.
- **Proportion of net costs:** Take the net cost for each diabetic spell beginning on that admission date and sum them, denote this by  $c_d$ . Do the same with the net cost of all spells with that admission date and denote this by C. Then the proportion of net costs spent on diabetic patients is given by  $\frac{c_d}{C}$ .

The obvious benefit of taking the quantities in this way is that it allows for the data to be arranged with some sense of time, but there is a glaring issue. That being that the data will be misrepresented when manipulated in this way. For instance, the length of a spell has no definitive connection to the admission date of that spell. By grouping all the spells starting on that day together and taking their mean, any adversely long spells will push the mean upwards. Also, there is a time-related error when taking the net cost of a spell on any one day in that spell since that cost was not truly spent or incurred on that day necessarily.

Irrespective of these misrepresentations, Figures 23 - 25 show how these quantities evolve over the entire data period. In each case, the monthly and year means are shown, and the standard deviation of the monthly averages in a year are given as error bars. The data has been aggregated into monthly and yearly averages rather than using the daily, or evenly weekly, data in an attempt to smooth out the misrepresentation that is described

above. In addition to these plotted points, the data has been fitted with a standard linear regression model - the statistics of which are given beneath the legend in each plot. These statistics are the R-squared value and standard error. These statistics help to describe the goodness of fit of the model and their definitions are given below.

**Definition 3.** Consider a dataset with n values, denoted by  $x_1, \ldots, x_n$ . Each of these data points has associated with it a predicted value obtained from the fitted model, denoted by  $y_1, \ldots, y_n$ . Let the mean of the dataset be denoted by  $\bar{x}$ . The coefficient of determination, denoted by  $R^2$ , is defined to be:

$$R^{2} = 1 - \frac{\sum_{i=1}^{n} (x_{i} - y_{i})^{2}}{\sum_{i=1}^{n} (x_{i} - \bar{x})^{2}}$$

Intuitively, the R-squared value represents the proportion of variation in the data that is explained by the model fitted, and thus should take a value in the interval [0,1].

**Definition 4.** Consider a dataset with n values,  $x_1, \ldots, x_n$ , and their corresponding predicted values,  $y_1, \ldots, y_n$ . Then the standard error of the estimate, denoted by SE, is defined to be:

$$SE = \sqrt{\frac{\sum_{i=1}^{n} (x_i - y_i)^2}{n}}$$

The standard error represents the average distance (error) of the data points from the regression line. The benefit of this statistic is that it gives a measure of the precision of the model on the scale of the variable that has been predicted.

Figures 23 & 24 suggest that the amount of resources consumed by the diabetic population is increasing, though slowly. The former indicates that on average the number of diabetic patients visiting the hospital is increasing slowly (approximately a one percent increase over five years), and from the latter it is seen that the yearly average proportion

of net spending on diabetic patients has also experienced a shallow increase of roughly half a percent over the same period. So, indeed, these plots give evidence to support the claim.

In addition to this, both figures show a distinct divergence as time progresses as shown by both the spread in the monthly averages and the widening of the yearly error bars. This is an interesting phenomenon; there seems no apparent reason for this variability to increase in recent years with improved policy on prevention, diagnosis, management and treatment [4].

With the final figure in this section it is clear that - despite the slight increase in the proportion of net costs and the number of diabetic admissions over the last five years - there has been a distinct decline in the average length of stay for diabetic patients in the same period. This average has fallen from one week to roughly five and a half days. This decrease is likely due, in part, to the changes in NHS policy referenced above but also the ever-increasing pressure put on the hospital system to move patients through the system efficiently in order to save on idle costs such as ward costs and overheads.

Across all three of the models summarised in the previous three figures, it is clear that none exhibit a particularly strong goodness of fit; though they all have appropriately small standard errors, the coefficients of determination are moderate at best (in the case of admissions and length of stay) and minuscule (in the case of net costs). This indicates that the models themselves are not wholly suitable in any case.

It is notable, also, that there is a seasonal pattern in each of the plots which is consistent with the linear models not performing well. The inclusion of seasonal behaviour in a regression model has more to do more with the semantics of finding a "good" regression model than was intended here but it is an important concept nonetheless. If the purpose of this exercise was to accurately predict the quantities being plotted rather than just seeing the general trend, then a more elaborate model would have been fitted.

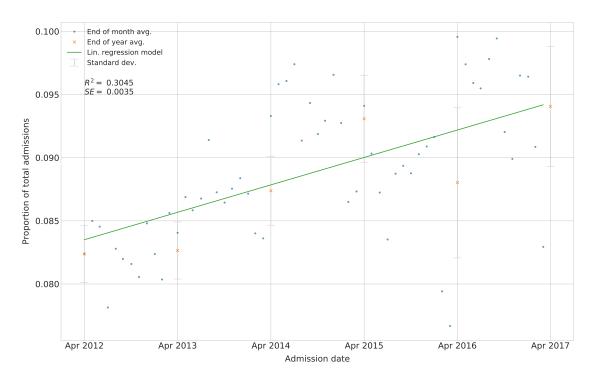

Figure 23: Monthly averages for the proportion of daily admissions presenting diabetes. Fitted with a linear least-squares regression model.

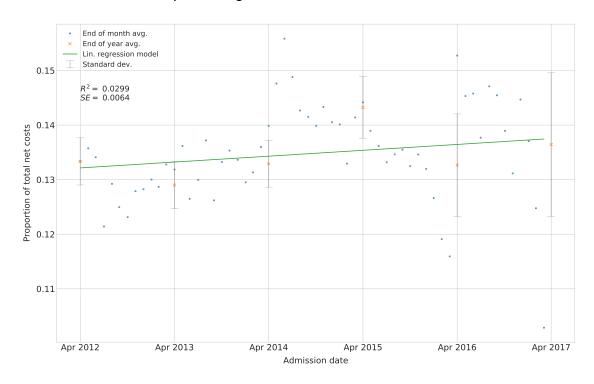

Figure 24: Monthly averages for the proportion of daily net cost spending toward diabetic patients given their admission date. Fitted with a linear least-squares regression model.

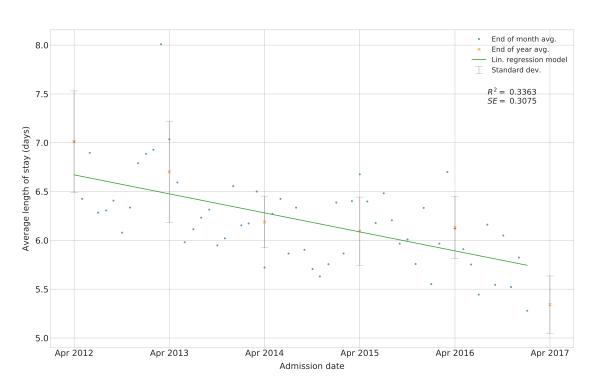

Figure 25: Monthly averages for the average length of a diabetic patient's spell given their admission date. Fitted with a linear least-squares regression model.
